the low cellularity of the SF, induced us to continue to suspect septic arthritis.

Serratia marcescens septic sternoclavicular joint arthritis: A case report

Artritis séptica esternoclavicular por Serratia marcescens: a propósito de un caso

To the Editor,

Septic arthritis of the sternoclavicular joint accounts for less than 1% of all the cases of septic arthritis. It is frequently associated with predisposing conditions, such as intravenous drug abuse or diabetes. Given the infrequency of the disease, the diagnosis is often delayed.1 Serratia marcescens is a Gram-negative enterobacterium associated with a wide range of nosocomial infections.2

We report a case of sternoclavicular joint septic arthritis caused by this enterobacterium. The patient was a 70-year-old man diagnosed with hypertension, type 2 diabetes, dyslipidemia and chronic ischemic heart disease in the form of unstable angina, with percutaneous revascularization of anterior descending and circumflex arteries. On admission to the hospital for unstable angina, catheterization revealed no evidence of new coronary lesions. On his left shoulder and dysphagia. On clinical examination, the only notable findings were an arterial blood pressure of 150/76 mmHg, body temperature of 38 °C, edema and erythema in left sternoclavicular joint, and pain on moving his left arm. The analytical findings included a hemoglobin level of 11.2 g/dl. and leukocyte count at 3600/mm³, with 7.5% lymphocytes and 83.8% neutrophils, platelet

count of 84,000/mm³ and C-reactive protein at 325 mg/L. Blood cultures revealed the presence of Serratia marcescens sensitive to quinolones, carbapenems, aminoglycosides and third-generation cephalosporins. Computed tomography of his neck and chest (Fig. 1) confirmed the presence of an infectious process in the sternoclavicular joint, with no signs of local complications. The results of an otorhinolaryngological examination were normal. It was not possible to obtain a sample of joint fluid. There was no evidence of endocarditis on transthoracic echocardiography. He was treated with 1 g/day of intravenous ertapenem for 4 weeks, followed by a

Fig. 1. Augmentation of soft tissue and obliteration of fat planes associated with the inflammatory-infectious process in left sternoclavicular joint (arrows).

2-week regimen of oral ciprofloxacin (500 mg/12 h). In view of the favorable clinical response and analytical findings, surgical treatment was ruled out.

Septic arthritis of the sternoclavicular joint is an uncommon disease in both immunocompetent and immunocompromised individuals. The risk factors are diabetes mellitus, rheumatoid arthritis, intravenous drug abuse, neoplastic diseases, chronic kidney disease, human immunodeficiency virus infection, cirrhosis, local trauma and central line infections. The fact that our patient was a diabetic and, moreover, had undergone cardiac catheterization is important. Staphylococcus aureus is the most common causative agent. Until now, there has been only one case attributed to infection by Serratia marcescens in the medical literature. The most common mechanism of infection is bacteremia. Patients may complain for days or even months of pain in shoulders, neck or chest, with limited arm mobility, associated with fever. The clinical picture in our patient was similar to those reported by other authors. However, we consider that the dysphagia was related to extrinsic compression of the esophagus. Joint inflammation and erythema can also be present. Septoclavicular arthritis is generally unilateral, and is right-sided in 60% of the cases. Bacteremia is found in 62% of the patients. Computed tomography is the initial imaging technique that can identify bone involvement and detect retrosternal dissemination. The most serious complication is mediastinitis, which occurs in 15% of the cases. The initial therapeutic approach includes prolonged antibiotic therapy when there are no complications. However, in the presence of extensive osteomyelitis, abscesses or mediastinitis, surgical treatment is recommended.

Debridement is the surgical technique associated with the lowest incidence of complications. In conclusion, septic arthritis of the sternoclavicular joint is uncommon, especially that caused by enterobacteria. However, it is potentially disabling and fatal, and should be suspected in any condition that affects the sternoclavicular region.

When she presented to our hospital, the patient was being treated with 5 mg prednisone and 150 mg ranitidine. On physical examination, she had pale skin and mucous membranes, deformed metacarpophalangeal and interphalangeal joints, and splenomegaly. Her laboratory tests were normal, with the exception of a leukocyte count of 1.82 × 10^9/L; neutrophils, 0.877 × 10^9/L; iron deficiency anemia; platelets, 130 × 10^9/L; complement C3, 70.9 mg/dL; complement C4, 5.1 mg/dL; and positive antinuclear antibodies with a homogeneous pattern. Oral iron therapy and weekly methotrexate were started and her prednisone dose was raised. In view of the clinical course (especially RA and neutropenia), as well as the presence of splenomegaly, we considered a diagnosis of Felty’s syndrome (FS). Computed tomography confirmed the splenomegaly and a bone marrow study revealed the presence of an interstitial and nodular infiltrate of T lymphocytes expressing CD3, CD8, T-cell receptor (TCR) βF1, and CD57, suggestive of infiltration by LGL leukemia. Four months after the initiation of treatment with methotrexate, the patient developed an abdominal wall abscess requiring antibiotic therapy and surgical drainage.

Large granular lymphocytic leukemia is an uncommon clinical condition, characterized by an indolent, nonprogressive clinical course. The symptoms present during the sixth decade of life, and it affects both sexes equally. It constitutes 2–5% of all T/natural killer (NK) cell neoplasms. To date, 400 cases have been reported in the literature. Given the criteria established for LGL leukemia, which require the presence of clonal expansion of LGL in peripheral blood >0.5 × 10^9/L and/or bone marrow and a study showing

Rheumatoid arthritis and T cell large granular lymphocyte leukaemia: A case report**

**Artritis reumatoide y leucemia de linfocitos grandes granulares T. A propósito de un caso**

To the Editor,

Large granular lymphocytic (LGL) leukemia was described by Loughran et al. in 1985. It is characterized as an unusual heterogeneous disorder with clonal expansion of mature T lymphocytes. Although the cause is unknown, antigen stimuli responsible for inducing the activation of large granular CD8+ effector lymphocytes via different signaling pathways have been implicated. It has been associated with a wide spectrum of signs and symptoms that can be the first or only manifestation of the disease, including asymptomatic periods, splenomegaly, cytopenias, recurrent bacterial infections, B symptoms, hepatomegaly, lymph node involvement, neuropathy and pulmonary hypertension. In addition, an association has been established between LGL leukemia and autoimmune diseases, forming part of an entity known as pseudo-Felty’s syndrome. We report the case of a 62-year-old woman who developed LGL leukemia 30 years after being diagnosed with seronegative rheumatoid arthritis (RA).
