Imaging in Myositis Ossificans: Bone Scintigraphy and 18F-fluorodeoxyglucose Positron Emission Tomography/computed Tomography

Myositis ossificans is a heterotopic calcification consisting of the transformation of primitive mesenchymal cells, present in the muscle connective tissue, into osteogenic cells. This disorder can be hereditary, and can affect up to 2 children per million or, to a larger extent, be acquired secondarily to orthopedic and traumatic injuries, with greater incidence during the second and third decades of life. It is associated with skeletal anomalies, erythema, reduction of joint mobility and can mimic the clinical presentation of cellulitis, osteomyelitis or thrombophlebitis.

We report the case of a 66-year-old man, with a history of hematoma involving fibrous tissue. He underwent an intervention in left thigh, while in orthopedic follow-up. We performed bone scintigraphy after the administration of 815 MBq of $^{99m}$Tc-hydroxymethylene-diphosphonate. We observed an abnormal increase in the osteoblastic activity in soft tissues of the midle and proximal third of left thigh up to left hip, with uptake of the tracer in the region of adjacent soft tissues and changes in normal bone morphology (Fig. 1A) compatible with myositis ossificans. After a course of several years, and in the clinical context of a lesion suggestive of a lung neoplasm, we performed positron emission tomography-computed tomography (PET/CT) after administration of 370 mBq of 18-fluorodeoxyglucose (18F-FDG). We observed several accumulations of the radiotracer that were distributed by the posteroinferior planes of the left buttock up to the middle third of the ipsilateral thigh (Fig. 1B), with a maximum standardized uptake value (SUVmax) of 9.1 in relation to a lesion with a highly heterogeneous morphology, with areas that were calcified, hypodense and formed by soft tissues. These findings would correspond to myositis ossificans located exactly beneath the tip of the greater trochanter. Unlike metastatic calcifications, that are associated with a change in the calcium phosphate metabolism, myositis ossificans can appear as a complication of muscle injury with hematoma secondary to inflammation of the fascia following a neurological lesion, surgery, traumatic injury or a burn.

Although it is not a frequent finding in PET/CT studies, some investigations provide evidence of its use as a suitable tool in the evaluation of biological activity in soft tissues.

Treatment depends on the degree of functional involvement, based on approaches involving radiotherapy, nonsteroidal anti-inflammatory drugs or diposphonates with preventive intention, or surgical resection and rehabilitation in established cases.
